19 Received 7 July 2010  
20 Revised 17 December 2010

21 The heart beat RR intervals extracted from the electrocardiogram recorded during the  
22 stress test show a non stationary profile consisting of a decreasing trend during the  
23 exercise phase, an increasing trend during the recovery and a global minimum (acme). In  
24 addition this time series exhibits a time-varying variance. We decompose the series into a  
25 deterministic trend and random fluctuation. The trend is obtained as an exponential fit  
26 of the data; the fluctuation is modeled as a mean reverting process driven by the trend,  
27 in which the random innovation has a time-varying variance. Data analysis, performed  
28 on ambulatory recorded electrocardiograms of 10 healthy subjects, shows that the model  
29 describes correctly the data series on a scale of at least 300 beats.

30 *Keywords:* Time series; mean reversion; heart rate variability; exercise test; heart beat;  
31 RR interval.

32 **1. Introduction**

33 The exercise stress test is routinely performed to evaluate the presence in the elec-  
34 trocardiogram (ECG) of myocardial ischemia. In the multistage Bruce protocol [1]  
35 the patient on a bicycle ergometer is subjected to a workload increasing in time by  
36 steps (25 W every 2 minutes). The exercise is stopped when the heart rate reaches  
37 a maximum, usually 85% of the estimated top heart rate based on the patient's  
38 age. After achieving peak workload, the patient spends some minutes at rest on the  
39 bicycle until his heart rate recovers its basic value. During the test 12-leads ECG

2 *C. Cammarota & M. Curione*

1 is monitored and diagnosis of ischaemia is usually performed by visual inspection  
2 of the ECG signal.

3 The exercise induces strong modifications of the heart rate reflecting the control  
4 of the neuroautonomic system. The heart rate is measured beat-to-beat from the  
5 reciprocal of the duration of a complete cardiac cycle, defined as the interval between  
6 two consecutive R peaks in the ECG (RR interval). The RR time series recorded in  
7 the stress test shows a non stationary behavior that can be qualitatively described  
8 as follows. We refer as a typical example to Fig. 1.

- 9 (1) The RR sequence shows two different types of trend: a decreasing one during  
10 exercise (stress phase) and an increasing one during recovery (recovery phase);  
11 these two phases are separated by a global minimum (acme).  
12 (2) The sequence shows a time dependent variability, that is larger when RR inter-  
13 vals are larger.

14 In the analysis of the heart rate time series the variability of RR intervals is  
15 known as the Heart Rate Variability (HRV) [2]. This variability is quantified by

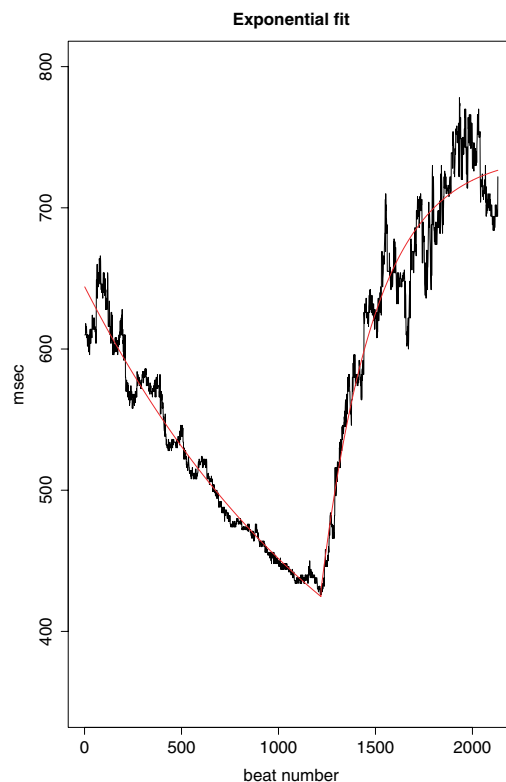

Fig. 1. Sequence of RR intervals (in msec) of a normal subject versus the beat number obtained with the Bruce protocol exercise test. The exponential trend is added.

1 means of several indices both in time and in frequency domain, and it is used to  
2 extract information on the control of the autonomic nervous system on heart rate.  
3 The HRV indices are usually evaluated on RR sequences recorded at rest, when  
4 the sequence can be supposed to be stationary or from 24 hours Holter monitoring,  
5 where analysis on several time scales can be performed.

6 Evaluation of HRV indices during exercise has been less frequently performed.  
7 In clinical studies a first type of approach focuses on the trend component of the RR  
8 intervals in recovery: a heart rate recovery of less than 12 beats per minute in the  
9 first minute was found to be a predictor of overall mortality [3]. A second approach  
10 removes baseline trend induced by exercise in the RR series using a suitable filter  
11 and then evaluates HRV on the residual. Several indices estimated over intervals of  
12 two minutes were found to be predictors of cardiovascular mortality [4]. Nevertheless  
13 the authors of [4] point out that the results during exercise contrast to results of  
14 HRV during rest, both in time and in frequency domain, concluding that the current  
15 explanations for the physiologic genesis of HRV at rest do not necessarily extend  
16 to exercise testing.

17 In the context of time series modeling evaluations of HRV have focused on compar-  
18 ison of exercise to rest. The complexity of heart rate was found to be less during  
19 and after a training camp of athletes than before [5]. In [6] differences in corre-  
20 lation properties are found between rest and exercise. In [7, 8], where the cardio-  
21 respiratory synchronization is investigated during, before and after exercise, it is  
22 observed a reduced variability of RR intervals and a reduction in synchronization  
23 during exercise with respect to rest.

24 In the experimental setting of previous papers the workload during exercise  
25 is constant in time. Data from the diagnostic protocols are characterized by a  
26 workload increasing in time. The RR time series so obtained are an example of  
27 a non stationary series for which novel mathematical techniques should be useful.  
28 A first attempt to investigate these data is in [9] where time-frequency methods  
29 of signal analysis were applied to estimate how low frequency and high frequency  
30 spectral components vary in time. In application to real data very low frequencies  
31 have been filtered out. An analysis based on a non parametric approach (analysis  
32 of extrema) is in [10]. The earlier references show the usefulness of information  
33 contained both in trend (heart rate recovery) and in residuals after detrending  
34 (time and frequency domain indices), but have not addressed the mathematical  
35 modeling of the observations in points (1) and (2) above.

36 The source of variability of RR intervals includes both purely stochastic compo-  
37 nents and deterministic ones related to the multiple interactions of the cardiac  
38 system of which the cardiorespiratory interaction plays a dominant role. This inter-  
39 action has been widely investigated, using mathematical models, in various condi-  
40 tions of breathing during rest (see for instance [11]). The dynamics of RR intervals  
41 during spontaneous breathing reveal both a deterministic behavior in the so-called  
42 “angular component”, and a random one in the “radial component” [12]. According  
43 to the results in [8] the cardiorespiratory interaction is reduced during the exercise

4 *C. Cammarota & M. Curione*

1 (constant workload of 50 Watt) with respect to rest, so that when the workload is  
 2 increasing its contribution to the RR variability should be even smaller. In addition  
 3 the strong deterministic trend in data recorded during increasing workload can  
 4 mask the other sources of variability in RR series, modeled as low-frequency noise  
 5 in [8].

6 So it is natural to consider a stochastic model for the fluctuations as a candidate  
 7 to describe some other features of the RR series as the time dependent variability  
 8 (point (2) above). This time dependent variability was already observed in atrial  
 9 fibrillation as a dependence of the RR variance on the RR mean in 24 hours Holter  
 10 recording ([13, 14]). The time varying variance has been used in [15] to model  
 11 volatility in non stationary financial series. Stochastic models of RR fluctuations  
 12 have been recently used in different situations ([16, 17]). As to point (1) mathematical  
 13 models of non stationary series include the notion of “mean reversion”, widely  
 14 used to model the economic time series (see for instance [18]).

15 The first aim of the present report is to formulate a model of the RR sequence  
 16 that explains the observations (1) and (2) above. We use the classical theory of  
 17 time series [19] based on the decomposition of the series in two main components:  
 18 deterministic trend and stochastic fluctuations. The model can be summarized as  
 19 follows:

- 20 • The trend is obtained using a simple mechanical model related to the workload.
- 21 • The stochastic fluctuations are modeled by a mean reverting process driven by  
 22 the trend.
- 23 • The time varying variance is modeled using a random innovation whose amplitude  
 24 is modulated by a smooth time varying scale factor.

25 The second aim is to describe the series using a small number of parameters  
 26 obtained from the model, that could be used to improve the diagnostic. Accordingly  
 27 model estimation and validation is performed on real data series extracted during  
 28 the routine ambulatory stress test. In this report we analyze 10 normal subjects  
 29 who underwent to the test performed according to the Bruce protocol.

## 30 2. The Model

31 We model the observed RR time series as the realization of a sequence of continuous  
 32 random variables (r.v.)  $X_1, \dots, X_n$ , where  $X_t$  denotes the RR interval at the  $t$ th  
 33 beat. The model is defined according to the following dynamical equation:

$$34 \quad \Delta X_t = -k(X_t - \alpha_t) + \sigma_t \epsilon_t; \quad t = 1, 2, \dots, t_2 - 1. \quad (1)$$

35 Here  $\Delta$  is the difference operator,  $\Delta X_t = X_{t+1} - X_t$ ,  $k$  is a positive constant, the  
 36 sequences  $\alpha_t$  and  $\sigma_t$  are, respectively, the trend and the time-varying variance and  
 37  $t_2$  is the number of beats. Both  $\alpha_t$  and  $\sigma_t$  are to be considered slowly variable at a  
 38 small time scale (few beats). The stochastic fluctuation is defined by  $\epsilon_t$ , a sequence  
 39 of independent and identically distributed (i.i.d.) r.v. with zero mean. The model

1 is constructed starting from a basic random walk of equation  $\Delta X_t = \sigma \epsilon_t$ , with  
 2 addition of a mean reversion term,  $-k(X_t - \alpha_t)$ , that drives the random walk  
 3 towards the deterministic trend  $\alpha_t$ . The scale factor  $\sigma_t$  models the time-varying  
 4 variance.

5 Given the initial value  $X_1$  and the values of the parameters the equation defines  
 6 a data generating process that can simulate the system. Equation (1) is a finite  
 7 difference stochastic equation of Langevin type. The investigation of its theoretical  
 8 properties is outside the scope of the present report and it is to our knowledge, not  
 9 easy. We now consider in detail the components of the model.

## 10 2.1. Trend

11 The RR series shows a global minimum called “acme” whose value is denoted  $m$ .  
 12 We define as “stress phase” the sequence of beats before the acme and as “recovery  
 13 phase” the ones after the acme. The duration of the stress phase is  $t_1$  beats; the  
 14 global duration is  $t_2$  beats; typical values are  $t_1 = 1500, t_2 = 2500$  (see Table 1).

15 We model the trend as a function  $\alpha(t)$ , solution of a differential equation, where  
 16  $t$  is a real number in the interval  $[0, t_2]$ . Both phases are characterized by a restoring  
 17 term that drives the system towards an equilibrium value  $M$ . For sake of simplicity  
 18 we assume that this term is linear:  $-a(\alpha - M)$ , where  $a$  is a positive constant. Since  
 19 the two phases may be characterized by different values, we shall use the notations  
 20  $a_1, a_2, M_1, M_2$ . In addition the stress phase is characterized by a constant negative  
 21 contribution  $-b$ , that quantifies the workload and produces a decreasing of the RR  
 22 intervals. We assume  $\alpha(t)$  to be solution of the two following ordinary differential  
 23 equations in different time intervals

$$24 \begin{aligned} \alpha'_1 &= -a_1(\alpha_1 - M_1) - b \\ \alpha_1(0) &= M_1; \quad t \in [0, t_1], \end{aligned} \quad (2)$$

Table 1. Parameters of the RR series: from left:  $t_1$  duration in beats of the stress phase,  $t_2$  total duration in beats of the test,  $m$  minimum RR in msec,  $M_1$  maximum RR in stress in msec,  $M_2$  maximum RR in recovery in msec.

$t_1$	$t_2$	$m$	$M_1$	$M_2$

1147	2062	395	678	723
1219	2131	421	610	696
2030	3097	365	492	594

6 *C. Cammarota & M. Curione*

$$1 \quad \begin{aligned} \alpha_2' &= -a_2(\alpha_2 - M_2) \\ \alpha_2(0) &= m; \quad t \in [t_1, t_2]. \end{aligned} \quad (3)$$

2 These equations have exponential solutions:

$$3 \quad \alpha(t) = \begin{cases} M_1 - \frac{b}{a_1}(1 - e^{-a_1 t}), & t \in [0, t_1], \\ M_2 + (m - M_2)e^{-a_2(t-t_1)}, & t \in [t_1, t_2]. \end{cases} \quad (4)$$

4 Obviously we cannot solve explicitly Eqs. (2) and (3) since we do not know the  
5 values of the parameters. We estimate these parameters fitting the data series by  
6 the formula in Eq. (4). This will be accomplished in Sec. 3, and the value of the fit  
7 for each  $t = 1, 2, \dots, t_2$  is denoted  $\alpha_t$ . An example of this exponential trend is in  
8 Fig. 1.

### 9 **2.2. Mean reversion**

10 The role of the mean reversion term  $-k(X_t - \alpha_t)$  is to drive the system towards the  
11 deterministic trend  $\alpha_t$ . For instance if the random innovations put the system above  
12  $\alpha_t$  the subsequent increment  $\Delta X_t$  is negative. The coefficient  $k > 0$  measures the  
13 speed of reversion. The estimate of this parameter can be done only after having  
14 estimated the trend  $\alpha_t$ . More precisely we consider as an independent variable the  
15 values  $X_t - \alpha_t$  and as a dependent one the values  $\Delta X_t$  (since the sequence  $\Delta X_t$   
16 has an element less than  $X_t - \alpha_t$  we cut the last element of the latter). From the  
17 scatter plot of the points defined, the slope of the linear fit gives an estimate of  
18 the parameter  $k$ . Of course for the validation of the model one has to verify that  
19 the intercept coefficient is not significantly different from zero, while the slope is a  
20 negative number significantly different from zero. This term can explain the large  
21 fluctuations around the trend that are mainly observed for large RR (Fig. 1).

### 22 **2.3. Time-varying variance**

23 After having estimated the parameter  $k$ , we define the sequence

$$24 \quad \eta_t = \Delta X_t + k(X_t - \alpha_t), \quad (5)$$

25 so Eq. (1) becomes

$$26 \quad \eta_t = \sigma_t \epsilon_t. \quad (6)$$

27 Squaring and taking logarithms we get

$$28 \quad \log(\eta_t^2) = \log(\sigma_t^2) + \log(\epsilon_t^2). \quad (7)$$

29 Examples of sequences  $\eta_t$  and  $\log(\eta_t^2)$  are in Fig. 2 (first and second panels, where  
30 only the stress phase is reported). From the plot of  $\log(\eta_t^2)$  we argue that a linear  
31 regression with respect to time is reasonable:

$$32 \quad \log(\eta_t^2) = c + dt + \gamma_t, \quad (8)$$

Modeling Trend and Time-Varying Variance of the Heart Beat RR Intervals During Stress Test 7

Fig. 2. Stress phase. First panel: The  $\eta_t$  sequence; second panel:  $\log(\eta_t^2)$ ; third panel  $\epsilon_t$ .

1 where  $c$  and  $d$  are constants coefficients and  $\gamma_t$  represents the random error term.  
 2 We estimate the coefficients using the standard least squares method (Table 2). We  
 3 are mainly interested in the sign of  $d$ , since  $d < 0$  (in the stress phase) implies (see  
 4 below) that the scale function  $\sigma_t$  is decreasing in time (during stress), as expected.  
 5 The data points (Fig. 2, second panel) are not symmetrically distributed around  
 6 the linear fit, or in other words the distribution of  $\gamma_t$  is not symmetric around zero.  
 7 In presence of a departure from normality we are not able to compute a confidence  
 8 interval of  $d$  using standard methods; this point is outside the scope of the paper.

Table 2. Estimated parameters of the model: stress (left) and recovery (right). From the left in stress:  $a_1$  speed of reversion to equilibrium (beat<sup>-1</sup>),  $b$  workload (msec/beat),  $k_1$  speed of reversion to trend (adimensional),  $c_1$  intercept (adimensional) and  $d_1$  slope (adimensional) of logarithmic time varying variance,  $e_1$  standard deviation of the error term (msec). From the left in recovery: the same without workload.

$a_1$	$b$	$k_1$	$c_1$	$d_1$	$e_1$	$a_2$	$k_2$	$c_2$	$d_2$	$e_2$

8 *C. Cammarota & M. Curione*

1 Hence we get

$$2 \quad \sigma_t = e^{\frac{1}{2}(c+dt)} \quad \epsilon_t = e^{\frac{1}{2}\gamma t} \text{sgn}(\eta_t). \quad (9)$$

3 Notice that the square of  $\eta_t$  in Eq. (7) causes to lose the information on the sign  
4 of  $\epsilon_t$ ; the sign is recovered from  $\eta_t$  in Eq. (6). One could choose  $\epsilon_t$  of unit variance  
5 just dividing for its standard deviation, after having estimated it; consequently the  
6 scale function  $\sigma_t$  should be multiplied by this constant.

### 7 **3. Estimation of the Parameters and Data Analysis**

8 For the aims of the present study we have selected 10 healthy subjects from a  
9 group referred for symptoms and signs suggestive of myocardial ischemia to ECG  
10 Laboratory during a recent study [20]. They underwent clinical examinations and  
11 scintigraphy; the standard 12-leads ECG was recorded during all the Bruce proto-  
12 col exercise test. It was used PC-ECG 1200 (Norav Medical Ltd.), which provides  
13 in output digital signal with resolution of  $2.441 \mu\text{V}$  and 500 Hz sampling frequency.  
14 The duration of the test was about ten minutes both for stress and recovery. These  
15 two durations are conditioned by two factors: the heart rate and the physical perfor-  
16 mance of the patient; evaluation of possible dependency between the two durations  
17 was outside the aims of the present work.

18 Pre-processing was performed on the raw data. For the RR extraction the pre-  
19 cordial lead V5 was chosen, because it is less influenced by motion artifacts. The R  
20 peak detection was performed using a derivative-threshold algorithm. Ectopic beats  
21 were absent or less than 1% of the total beats for each subject. Some missed beats  
22 produced RR intervals outside the normal range. A filtering algorithm replaced  
23 these intervals with the median computed over blocks of 30 adjacent beats. In our  
24 study we have adopted the usual method in HRV literature to consider the beat  
25 number and not the real time as the independent variable in the RR time series.  
26 The real time scale of the experiment can be recovered from the RR series, just by  
27 summation of the RR intervals.

28 Analysis of raw data, R peak detection, and subsequent computations were  
29 performed using the free statistical software R [21].

30 The parameters  $m, M_1, M_2, t_1, t_2$  are estimated just by observation of the time  
31 series. In particular  $M_1, M_2$  are estimated by the mean of 20 values of the series at  
32 the start of exercise and at the end of recovery, respectively. A more subtle point  
33 is the estimation of the acme, and, in particular, of the beat number  $t_1$ . To do this  
34 the RR series is smoothed so that there is only one beat in which the series takes  
35 its minimum and this defines uniquely  $t_1$ . These values are reported in Table 1.

36 The parameters  $a_1, a_2, b$  are not observable directly and have to be estimated  
37 from the model. From Eq. (4) a rough estimate of the parameters  $a_1, a_2, b$  can be  
38 obtained. These values are then used as starting ones in a nonlinear least squares  
39 estimation of the same parameters from the data series. The values obtained are  
40 reported in Table 2. The exponential fitting obtained is satisfactory in all the cases  
41 considered; a typical one is in Fig. 1.

1 The parameter  $k$  is estimated as the slope of a linear fit of  $\Delta X_t$  with respect  
 2 to  $X_t - \alpha_t$ . From the fitting report this slope is negative with a very high level of  
 3 significance; the intercept is not significantly different from zero. In the estimation of  
 4 the time-varying variance parameters of Eq. (8) the main parameter  $d$  is significantly  
 5 different from zero.

6 The last parameter is the standard deviation of  $\epsilon_t$ , denoted  $e$ , which represents  
 7 the amount of random noise contained in the data. The values of the parame-  
 8 ters  $k_1, c_1, d_1, e_1$  for stress and the corresponding ones for recovery are reported in  
 9 Table 2.

#### 10 4. Model Diagnostics

11 The analysis of the residuals  $\epsilon_t$  shows at least qualitatively symmetry with respect  
 12 to zero, which is compatible with the hypothesis of zero mean (Fig. 2, third panel);  
 13 the quantile-quantile plot of the non normalized distribution versus a standard  
 14 normal (Fig. 3, first panel) shows a moderate departure from normality.

15 In order to test the assumption of independence of  $\epsilon_t$ , we have used the standard  
 16 methods of statistical time series analysis, for which we refer for instance to [19]. We  
 17 have first extracted sub series of  $\epsilon_t$  of 300 beats located in the middle of stress and

Fig. 3. Stress phase. First panel: The normal Q-Q plot of the sequence  $\epsilon_t$ ; second panel: the autocorrelation function of  $\epsilon_t$  for a segment of 300 beats.

1 recovery phases. For these sub series we have computed the autocorrelation function  
 2 (ACF). The plot of a typical ACF (Fig. 3, second panel) shows that the majority of  
 3 the values are inside the 95% confidence limits (dashed lines) and that only a few  
 4 values are nearly outside. In these cases it is usual not to reject the assumption that  
 5 the sequence is uncorrelated. In some nonlinear models of time series (for instance,  
 6 ARCH models of financial series) there is the following situation: the series is not  
 7 independent; the series has zero ACF; the squared series has non zero ACF. For  
 8 this reason we have computed the ACF of the sub series  $\epsilon_t^2$ ; the results are similar  
 9 to the ones of  $\epsilon_t$  and we conclude that also the ACF of the sub series of  $\epsilon_t^2$  is zero.  
 10 This rules out the possibility of this type of nonlinear models. We have also tested  
 11 the stronger assumption that the subseries  $\epsilon_t$  is an independent sequence. We have  
 12 used the runs test, a non parametric test that does not assume normality. The runs  
 13 test shows that the independence cannot be rejected at the 95% confidence level.  
 14 Hence we conclude that at least on the chosen temporal windows of 300 beats, the  
 15 i.i.d. assumption cannot be rejected.

16 The same tests for the entire series  $\epsilon_t$  (not reported here) show a significant  
 17 departure from the i.i.d. assumptions. We conjecture that this is caused by non sta-  
 18 tionary behavior that is still present, if much reduced, and that cannot be explained  
 19 by the model. This behavior depends on several factors. The first one is the depar-  
 20 ture of individuals features from the model, in particular for the exponential trend,  
 21 that is typical of medical data. A second one is the low resolution of the RR interval  
 22 measurement. Actually the RR values close to acme, where the variability is smaller,  
 23 have a very small range and are more similar to discrete r.v. than to continuous  
 24 ones. This can be seen at the right end of the  $\epsilon_t$  plot in the third panel of Fig. 2.  
 25 A third one is the cardiorespiratory interaction, that may modulate the variability  
 26 at the beginning of exercise and at the end of recovery (larger RR values).

27 At this stage of our findings the independence of the entire sequence  $\epsilon_t$  can be  
 28 assumed in the model defined by Eq. (1) only as a first approximation.

## 29 5. Conclusion

30 In our model of the RR series the trend is described by a simple (exponential)  
 31 sequence, and the fluctuations are decomposed into two contributions: the time  
 32 varying variance and the error term. The first one is in turn a simple (exponential)  
 33 scale factor and the second one is modeled as a random sequence. The model uses  
 34 a small number of parameters that describe some relevant features of the series, if  
 35 compared to the complexity of this type of data. The parameters of trend and time  
 36 varying variance reported in Table 2 show that there is an inter individual variabil-  
 37 ity, but this is in the typical range of medical data. Some essential parameters that  
 38 quantify the main features are rather homogeneous both in sign and in value.

39 The tests on the random sequence  $\epsilon_t$  show that over some intervals of 300 beats  
 40 this sequence can be considered as an independent sequence of r.v. Hence at  
 41 this stage the main information contained in this sequence are the two standard

1 deviations  $e_1$ ,  $e_2$  of stress and recovery in Table 2 . We notice that these are rather  
2 constant in the group of individuals, which is surprising in medical data.

3 The modeling of  $\epsilon_t$  as an independent random sequence cannot be extended to  
4 all the duration of the test. In particular for larger RR intervals we expect that  
5 the interaction of respiratory and other systems modulates the RR variability. This  
6 would be reflected in a non zero autocorrelation of  $\epsilon_t$ ; but to observe it one should  
7 have sufficiently long stationary conditions. This experimental setting characterized  
8 by a strong trend masks these modulations. It is not excluded that for larger RR  
9 intervals a more detailed analysis aimed to point out the deterministic behavior as  
10 the one in [12] could reveal the cardiorespiratory interaction.

11 Our results show that a great part of the information is contained in the non  
12 stationary behavior, i.e., the profiles of trend and time-varying variance. In those  
13 HRV studies, where indices are computed on the residuals obtained after detrending,  
14 a bias is introduced since there is another source of non stationarity, i.e., these  
15 residuals are non stationary in variance. This could explain the controversial results  
16 in [4].

17 While the actual clinical use of the stress test consists mainly in a visual inspec-  
18 tion of the ECG, the model provides a set of parameters that could lead to new  
19 clinical applications. Each comparison of a parameter during stress with the cor-  
20 responding one during recovery could be interesting. For instance parameters  $a_1$   
21 and  $a_2$  reflect the restoring force towards equilibrium in stress and recovery. These  
22 two phases are respectively prevalently under the influence of the sympathetic and  
23 vagal termination of neuroautonomic system, so that the parameters should pro-  
24 vide a quantification of these influences. The same for the pairs  $k_1, k_2$  and  $e_1, e_2$   
25 to which a physiologic meaning should be given. We have described the stepwise  
26 loading by a unique constant parameter, as a first approximation. A more accu-  
27 rate use of timing of the load and of the response could also provide interesting  
28 informations. A comparison between normal of the non normal cases could provide  
29 useful insights for instance in diagnosis of ischaemia. In these type of investigations  
30 a larger number of cases than the present one is required.

### 31 Acknowledgments

32 We thank the two reviewers for careful reading of the manuscript and stimulating  
33 comments.
